The transport of oxygen, water and naked ions of Na⁺ and Cl across two kind of hydrogels materials, made of a conventional hydrogel (Hy) based on hydroxyethyl methacrylate (pHEMA) and a silicone hydrogel (Si Hy) material containing siloxane moieties, was compared between Molecular Dynamics Simulations (MDS) and experimental measurements. Computer assisted simulations were carried out for wet hydrogels at 310 K and equilibrium water uptake in the range from 10% to 40%. Our results show that in Si Hy materials the aqueous hydrogel and hydrophobic siloxane phases are separated suggesting a co continuous structure, and oxygen moves predominantly through the free volume of the hydrophobic siloxane phase. The values of diffusion coefficient of O₂, water and Na⁺ and Cl ions in Si Hy was about one order of magnitude higher than in conventional hydrogels when the water content was above 25 wt% up to a critical value of 35 wt% where a percolation phenomenon is observed. The value of the oxygen diffusion coefficient obtained by simulations are roughly similar to that experimentally found using potentiostatic techniques. Values found experimentally for Na⁺ diffusion coefficients are between three or five times lower than MDS. For Si Hy materials with 36 wt% of water the Na⁺ permeability, diffusion coefficient and salt partition coefficient ($k_m=P/D$) are $6.7 \pm 0.2 \times 10^7 \text{ cm}^2/\text{s}$, $1.8 \pm 0.5 \times 10^6 \text{ cm}^2/\text{s}$ and 0.42 ± 0.13 , respectively. For Hy materials of 38.6 wt% the values found were $18.4 \pm 1.2 \times 10^7 \text{ cm}^2/\text{s}$, $5.4 \pm 1.0 \times 10^6 \text{ cm}^2/\text{s}$ and 0.34 ± 0.09 , respectively. The coordination number between the fixed groups (SiO) and water in HEMA and the particles (O₂, Cl and Na⁺) is slightly larger than unity. The present study might be applied in the modeling of the gas transport in hydrogels as well as in novel polymeric structures for novel polymeric structures for new biomedical and technological applications with the aim of predicting and tuning their physiological behavior.

1. Introduction

The gas permeability in polymer films and membranes are critical aspects in food packaging, protective coating, membrane separation processes and biomedical materials. With this purpose, hydrophilic polymers prepared from very different monomers have been widely investigated in the last 30 years given the vast field of their applications in contact lenses (CL), dental materials, optical lenses, materials for encapsulated cells, carriers for controlled drug delivery, or super absorbent hydrogels to be used in different domains of the technological, agricultural, or health industry [1–7]. Many different chemical structures constitute the base of these compounds, although the main component has a

hydrophilic character [8,9]. Particularly, hydrosoluble methacrylic monomers are employed very often to prepare wet hydrogels to be used as soft CL which represents over 90% of the global market of all lenses prescribed [10,11]. This kind of materials starting with the development of poly(hydroxyethyl metacrylate) (pHEMA) [10], and was followed by a variety of copolymers of HEMA and/or other hydrophilic or hydrophobic monomers, resulting in a diversity of ionic and non ionic hydrogels lenses with different water content [12,13]. The knowledge of the oxygen permeability, $P=DS$, where D and S are respectively the diffusion coefficient and solubility through CL, is one of the most important properties governing physiological response of the ocular surface during CL wear.

Silicones are polymers with a backbone consisting entirely of silicon oxygen bonds (siloxane), responsible for their high gas permeability [14]. Siloxane is now present in the most recent generation of CL known as silicone hydrogels (Si Hy), combining the softness and comfort of the p HEMA based hydrogels with

*Tel.: +34 963879328; fax: +34 963877329. E-mail address: vicommo@ter.upv.es (V. Compañ).

the higher oxygen permeability typical of siloxane containing materials. Some of these materials fulfill the requirements established to be worn under open and closed eye conditions [15] and have been a breakthrough in the contact lens industry representing now, over 70% of all lenses marketed in several countries worldwide [10,11].

There are few reports in the literature providing information on Molecular Dynamics Simulations (MDS) to obtain gas diffusion coefficient in wet hydrogels, but particularly the information regarding the calculation of gas solubility in these systems is scarce. This is due to the fact that the chemical potential, which plays the main role in the calculation of the solubility, is difficult to obtain in MDS. Eslami and Müller Plathe [16,17] made an exhaustive review of methods used to determine the solubility coefficient for molecular simulations. In glassy polymeric systems such as the membranes used for gas separation, in which the atomic motion is very restricted, the diffusion coefficients and solubility have been calculated by Gusev et al. [18] using the transition state approximation (TSA) method. Other authors computed the diffusion coefficient by the TSA method and gas solubility coefficient using modified Widom methods [19–25]. Monte Carlo methods and specially TSA have been widely used for determination of solubility and diffusion coefficients in rigid systems. All are based in the assumption that the only movements produced inside the host matrices are small atomic vibrations usually defined by a “smearing factor”. In a system where atomic mobility is high, e.g. in a hydrogel, the use of methods such as TSA would not be applicable as this smearing factor makes no sense. In rigid membranes, gas transport happens by mean of jumps between minimum energy positions and it is not depending on structural relaxation of polymer matrices but just depends on elastic movements of the matrix; this is only true for rigid membranes. In systems where atomic mobility is less restricted or present high gas diffusion such is the case of conventional Hy and Si Hy, the MDS is a very good method to determine the diffusion coefficient [26,27] but the determination of solubility coefficient in these systems is not fully developed. In most of these methods, the chemical potential is calculated at the end of the molecular dynamic run what complicates determination of equilibrium properties. We propose the implementation of molecular dynamic trajectory of modified particle insertion method for the study of wet hydrogels. To evaluate the method we have chosen two kinds of hydrogels based on pHEMA and Si Hy materials commonly used in the production of soft CL with different amounts of water absorbed.

Although not as well known as oxygen permeability, hydraulic and ionic permeabilities are very important to warrant an adequate relationship between the CL and the ocular surface. According to Domscheke et al. [28], ion permeability of contact lenses is a critical parameter for lens movement on the eye required for post lens tear

turnover and metabolic waste removal. Thus, both, oxygen and ion transport through Hy and Si Hy CL materials are critical properties.

In this work, the trajectories of naked Na^+ cations, Cl^- anions, H_2O and O_2 molecules are simulated using full MDS at 35 °C. The simulations were carried out for pHEMA based conventional hydrogels and Si Hy materials of similar composition to commercial CL with different water content proportions. Once the trajectories reach Einstein behavior, the diffusion coefficients are determined and a modified particle insertion method was used to determine the solubility coefficient of oxygen. The transport mechanism was explained for these systems. To proof the validity of our MDS we also measured experimentally the oxygen permeability, diffusion and solubility coefficients of different Hy and Si Hy materials used in commercial CL. Similarly, diffusion and ion permeability have been obtained in Hy and Si Hy CL materials. These kind of studies can have an important role for the design and prediction of CL material performance regarding the ionic diffusion and oxygen diffusion, permeability and transmissibility, as well as gas transports studies in other wet hydrogels.

2. Materials and methods

To evaluate the oxygen and ionic transport in Hy and Si Hy materials we have conducted MDS and performed experimental measurements. The following sections address the methodological approaches followed. To compare the simulation results with experimental results, the values of apparent oxygen permeability, diffusion coefficient, solubility and salt permeation have been measured in eight commercial contact lenses CL of the same class of those modeled compositions. Table 1 shows the main characteristics of commercial CL used in this study: commercial name, USAN material name and water content at saturation harmonic thickness for eight different materials of Hy and Si Hy CL. Four of them are Hy CL: Seequence (Polymacon), Proclear (Omafilcon A), Acuvue (Etafilcon A) and Newvues (Vifilcon A) manufactured by Baush&Lomb, CooperVision, Johnson&Johnson and Alcon (previously Ciba Vision), respectively. The other four are Si Hy CL: Pure Vision® (Balafilcon A), Biofinity (Confilcon A), Acuvue Oasys (Senofilcon A) and Avaira (Enfilcon A) manufactured by Alcon, CooperVision, Johnson&Johnson and CooperVision, respectively. The values of the water content at saturation, reported in Table 1, are provided by the manufacturers of the lenses. The harmonic mean thickness, L_{av} , of the lenses completely saturated of water, was measured using an electronic thickness gauge (model ET 3, Redher Development Co., Castro Valley, CA), with precision of $\pm 2 \mu\text{m}$. The results and standard deviation (SD) are given in the fourth column of Table 1. The solution of NaCl was provided from Sigma Aldrich and distilled/deionized water (DDI) was obtained from a MilliQ™ purification system with a resistivity greater than 18.2 MΩ cm.

Table 1

Properties of commercial contact lenses. L_{av} is the harmonic mean thickness of a lens completely saturated of water. The values of oxygen permeability (P), diffusion coefficient (D) and solubility (S) have been measured by a potentiostatic method following the procedure described in Section 2.2.

| Lens (commercial name) | Material | H_2O , wt% | L_{av} , μm | $D (\times 10^6)$, cm^2/s | $S (\times 10^5)^a$ | P , Barrer ^b |
|------------------------|--------------|----------------------------|--------------------------|--|---------------------|---------------------------|
| Seequence | Polymacon | 38.6 ± 1 | 95.2 ± 2.1 | 0.5 ± 0.1 | 18.0 ± 4.6 | 8.8 ± 0.5 |

2.1. Oxygen diffusion and permeability measurements

The diffusion characteristics of the lenses were determined utilizing a permeometer model 201T (Rheder Development Co.) commonly used to measure the oxygen permeability through CL.

In the permeometer, the oxygen permeates from one side of the wet hydrogel where the partial pressure of the gas is kept constant ($p=p_L=155$ mmHg) to the other side facing the cathode of the polarographic cell where the partial pressure is $p_0\sim 0$.

In steady state conditions ($t\rightarrow\infty$), the current intensity can be written as

$$I_\infty = \frac{nFADc_0}{t_{av}} \quad (1)$$

By assuming that Henry's law holds, $c_0=kp$ where p is the pressure of gas at the surface of the hydrogel facing the high pressure side in the experimental device, then Eq. (1) becomes

$$I_\infty = \frac{nFAPp_L}{t_{av}} \quad (2)$$

where n represent the number of electrons exchanged in the cathodic reaction ($n=4$), F is Faraday's constant and A the area of the cathode, t_{av} the average thickness and P the apparent permeability coefficient.

The apparent oxygen diffusion coefficients can be determined as

$$D = \frac{t_{av}^2 I_\infty}{6(I_\infty t - Q(t))} \quad (3)$$

By measuring $I(t)$ as a function of time the values of both the permeability and diffusion coefficients can be readily determined, respectively, by means of Eqs. (2) and (3).

More details and a sketch of the experimental assembly and measuring procedure are given elsewhere [29–31]. The technical characteristics of the CL measured and the experimental results of apparent permeability and diffusion coefficient are given in Table 1.

2.2. Ion Na^+ permeability measurements

The ionic permeability of Hy and Si Hy lenses can be determined following the experimental setup shown in Fig. 1. In the experimental cell, a lens was attached to the bottom of the donor chamber (A) filled with a volume of 16 mL of 0.1 M NaCl solution. Chamber (A) consists of a tube of 16 mm inner diameter, which was then placed in a receiving chamber (B) containing 100 ml of distilled/deionised (DDI) water (milli Q). The aperture communicating both donor and receiving chambers is 8 mm of diameter. The receiving chamber was on a magnetic and stirring heating plate thermostated at 35 °C to simulate physiological conditions.

Fig. 1. Illustrative experimental set-up to used to measure the salt permeability.

The conductivity of the solution in the receiving chamber (B) was monitored by a conductivity meter with temperature sensor incorporated (model: Crison CM 35).

Calibration of the conductivity probe was evaluated before each measurement experiment using different NaCl solutions of known concentration ranging 10^{-1} to 10^{-5} M. The receptor solution conductivity was monitored using a Crison CM 35 conductivity meter as a function of the time and subsequently converted to NaCl concentrations using the calibration plot. The salt permeability was calculated as follows [32]:

$$\ln\left(1 - \frac{2c_R(t)}{c_{L,0}}\right) = \frac{2AP}{V_R L}(t - t_0) \quad (4)$$

in which $c_R(t)$ is the concentration of sodium ions at time t in the receiving chamber, $c_{L,0}$ is the initial concentration of sodium ions in donor chamber, A is the area of the lens exposed to the salt flux, L represent the average lens thickness in the area exposed, V_R is the volume of the receiving cell compartment and P is the apparent permeability coefficient of the sodium ion ($P=Dk_m$, where k_m is the lens partition coefficient). If we take into account that the difference in concentration between both sides of the lens, $\Delta c=c_R - c_{L,0}$, is practically constant due to the fact that $c_R \gg c_{L,0}$, then

$$c_R = \frac{APc_{L,0}}{V_R L}(t - t_0) \quad (5)$$

Thus, plotting the concentration of Na^+ ions in chamber B vs. time allows us to obtain the apparent Na^+ permeability of the lens from the slope of Eq. (5). When the lens has high solute sorption capacity, there will be a time lag before the pseudo steady state is reached in the permeation experiment. From the curve of concentration vs. time, the time lag t_0 can be obtained from the intersection of pseudo state line with the x axis representing time [33]. The diffusion coefficient can be then estimated as

$$D = \frac{L^2}{6t_0} \quad (6)$$

3. Results and discussion

3.1. Computational details

Bulk structures of Polymacon (pHEMA based Hy material) and Balafilcon A (Si Hy material), with different water uptake rates and diffusing particles for diffusion calculations and without diffusing particles for solubility calculations, were packed into five different cubic boxes, with periodic boundary conditions (PBC) to provide an initial density of 1.1 g/cm^3 with cubic box size higher than $30 \times 30 \times 30 \text{ \AA}^3$ (Table 2). Materials used were selected to be similar with polymacon Hy material and Balafilcon A Si Hy material. While polymacon is now a well known material mainly made of pHEMA, the chemical composition of Balafilcon A is much more complex. However, it is known [15] that the monomer mainly responsible for the high oxygen permeability of Balafilcon A includes, among others, vinyl carbamate TRIS derivative tris (trimethylsiloxy)silylpropyl vinylcarbamate (TPVC). The TPVC molecule contains a hydrophobic silicone portion directly linked to a hydrophilic vinyl carbamate group. This latter moiety provides a significant hydrophilic character to the material. The TPVC molecule is soluble in different proportions with other hydrophilic monomers, such as HEMA and NVP (N-vinylpyrrolidinone). In addition, the vinyl carbamate group provides a “polymerization link” for attachment of hydrophilic monomers responsible for the water uptake of hydrogel and the Si Hy polymers [12,19]. The polymerization reaction of TPVC with NVP, using UV initiation

The monomer structures are the following.

methods, results in transparent, high Dk and relatively low modulus water insoluble gels.

All simulations of hydrated hydrogels in the box were accomplished using the discover module of Materials Studio 3.2 [34] molecular modeling package and the pcff91 force field with partial charges defined by force field was used in all calculations [34–38]. This force field has been found also suitable for modeling naked and hydrated protons in polyether systems (PES) with sulfonic acids [39–41]. The system structure energies were minimized with respect to all internal coordinates by a Conjugate Gradient method until the maximum derivative was smaller than 0.1 kcal/(Å mol), with a limit of 5000 steps; 500 ps of NVT MD controlled by means of the Andersen thermostat method with a collision ratio of 1.0 and 200 ps of NPT MD controlled by the Berendsen barostat method with a decay constant of 0.1 ps, at 310 K, were performed to obtain relaxed structures with the final system density. In these MD a 1 fs time step was used and Van der Waals and Coulombic non bonding interactions were calculated by the Ewald method [42]. Then, the system was subject to a stabilization process consisting on a 200 ps (2×10^{-10} s) long NVT MD run. The data collecting stage consisted of NVT MD runs of 5 ns for all systems. We consider this time large enough to reach a steady state in the study of dissemination of our simulations, and also sufficient to avoid the influence of the initial configurations in the calculation of solubility. Van der Waals and Coulombic nonbonding interactions were calculated by the cell multipole method (CMM) [43–45], the value of the update width parameter was 1.0 Å, and the accuracy parameter was set to medium to use third order terms in the Taylor series expansion and explicit interactions from more neighboring cells. The structural

results obtained by using the fast CMM methods for the cells agree with the results obtained with the slow Ewald summation method.

Diffusion coefficients D of diffusers in membranes can be calculated by the Einstein diffusion as

$$D = \frac{1}{6N} \lim_{t \rightarrow \infty} \frac{d}{dt} \sum_i^N \langle [R_i(t) - R_i(0)]^2 \rangle \quad (7)$$

The summation at over N the right hand side of the equation is called the *mean square displacement* (MSD). N is the number of diffusing particles, t is time and $R_i(t)$ is the position vector of an ion or molecule ($i = \text{O}_2$, H_2O , Na^+ , and Cl^-) at time event t . Average MSD curves as a function of time for each diffuser type were calculated. In general, the values of D decrease with increasing time increases, reaching a constant value at long times that reflects steady state conditions ($t \rightarrow \infty$). When the system reaches this situation the value of the diffusion coefficient is estimated and that indicates that the plot of $\log(\text{MSD})$ vs. $\log(t)$ in each case has a slope of 1 ± 0.03 , [46].

The solubility S of the diffusing gas in a host polymeric matrix could be evaluated as [18]

$$S = \frac{1}{kTV} \int \exp\left(-\frac{E(R, \varphi, \theta)}{RT}\right) dV = \frac{1}{kTN} = \frac{Z}{76N} \left(\frac{\text{cm}^3(\text{STP})}{\text{cm}^3 \text{ cmHg}}\right) \quad (8)$$

where k is Boltzmann's constant, V is the cell volume, E is the insertion energy and N is the number of random diffuser insertions, employed to compute the partition function Z .

The interaction energy between i and j atoms was computed by Van der Waals (9,6) proper of pcff91 force field and the diffuser

insertion energy, as the sum over all matrix atoms.

$$E(ij) = \varepsilon_{ij} \left[2 \left(\frac{r_{ij}^*}{r_{ij}} \right)^9 - 3 \left(\frac{r_{ij}^*}{r_{ij}} \right)^6 \right] \quad \text{with} \quad \varepsilon_{ij} = 2\sqrt{\varepsilon_i \varepsilon_j} \frac{r_i^3 r_j^3}{r_i^6 + r_j^6} \quad \text{and} \quad r_{ij}^* = \left(\frac{r_i^6 + r_j^6}{2} \right)^{\frac{1}{6}} \sqrt{a^2 + b^2} \quad (9)$$

These solubility calculations have been performed by the method of Widom [19] and modifications of this method proposed by us in the case of rigid polymer matrices [5], well below the glass transition temperature. In the case of a wet hydrogel these approaches are not viable because it seems appropriate to study the process of insertion of molecules considering that the atomic motion is not restricted. In this insertion process it was considered appropriate not to use presets, but to generate a random process of insertion in terms of position and orientation of guest molecules, and study the convergence to constant values of solubility. In this work, 5×10^6 random molecules insertions were performed over 100 conformations obtained by MD simulations and the energy of Eq. (9) was computed as Eq. (9) and is shown in Fig. 2. The insertion of one oxygen molecule could be defined by position vector of oxygen molecule center of mass, R , and, the polar coordinates of oxygen atoms respect to center of mass, ϕ , θ .

The transport mechanism of diffusers was investigated by computing intermolecular pair correlations functions $g_{AB}(r)$ which represent the probability of finding a pair of particles AB at a distance $r \pm dr$ normalized with respect to the probability

expected for a completely random distribution at the same density. Values of $g_{AB}(r)$ were evaluated as [34]

$$g_{AB}(r) = \frac{V}{(N_A N_B N_{AB})} \left\langle \sum_{i \neq j} \delta(\mathbf{r} - |\mathbf{r}_{Ai} - \mathbf{r}_{Bj}|) \right\rangle \quad (10)$$

where A and B represent two kinds of particles (e.g., individual atoms like Na^+ or Cl^- , atomic groups like H_2O , O_2 , etc.). The system has a volume V and contains N_A particles of kind A and N_B particles of kind B with N_{AB} particles belonging simultaneously to both kinds ($N_A = N_B = N_{AB}$ when computing correlation among particles of the same kind; for instance, correlation of the relative positions of ions). Vectors \mathbf{r}_{Ai} and \mathbf{r}_{Bj} represent the position of particle i of kind A and particle j of kind B , so that $|\mathbf{r}_{Ai} - \mathbf{r}_{Bj}|$ is the distance between those two particles. The $\delta(\mathbf{r} - |\mathbf{r}_{Ai} - \mathbf{r}_{Bj}|)$ term is set to unity when $(\mathbf{r} - |\mathbf{r}_{Ai} - \mathbf{r}_{Bj}|) \leq d\mathbf{r}$ (i.e., when the difference between desired and actual distance among the two particles is smaller than a tolerance factor $d\mathbf{r}$ and to zero otherwise).

3.2. Localization of O_2 , Cl^- , Na^+ and H_2O in soft contact lenses in MDS

The distribution of the oxygen molecules, Na^+ and Cl^- ions in the polymeric structure of the Hy and Si Hy materials was investigated by computing intermolecular pair correlations functions $g_{AB}(r)$ using Eq. (10). Figs. 3 and 4 show the pair correlation function between oxygen and water molecules in the Hy (pHEMA) and Si Hy systems. A close inspection of Fig. 3 shows that the oxygen atoms tend to be located in both areas (two phases), but they present a distance greater than one in the hydrophobic phase (siloxane phase). Therefore, they will be present in both phases but mainly in the hydrophobic one. Then, we hypothesize that in pHEMA systems (Hy), the oxygen molecules will be in both areas but mostly in the hydrophilic one. Fig. 4 plots the pair correlation function (PCF) vs. distance r (Å) to know if the Cl^- and Na^+ ions (A type atoms) are closer to type B (SiO , H_2O) or (pHEMA, H_2O) for systems with 37 wt% water. Fig. 4 clearly shows that chlorine ions are in the hydrophilic phase where the first solvation sphere can be observed around 3 Å and the second solvation sphere can be more diffusely seen around the 5–6 Å.

Fig. 5 shows the volume of VdW (Van der Waals) corresponding to polymer atoms and diffusing molecules for Hy and Si Hy of

Fig. 2. Position of oxygen molecule in the coordinate system within a given simulation cell.

Fig. 3. Plots of pair correlation function between oxygen and water molecules (black lines) and polymer molecules (red lines) in the pHEMA (a) and Si-Hy (b). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

10 and 37 wt% water content, respectively. From this figure, two types of domains can be observed in Si Hy matrices. The hydrophilic and hydrophobic phases are separately formed but they coexist and there is a continuous link between them. For example,

it can be observed that the aqueous and siloxane phases are separated and that oxygen moves mainly through the hydrophobic phase (siloxane phase) instead of through the hydrophilic phase, suggested to the fact that the hydrophobic phase must offer less

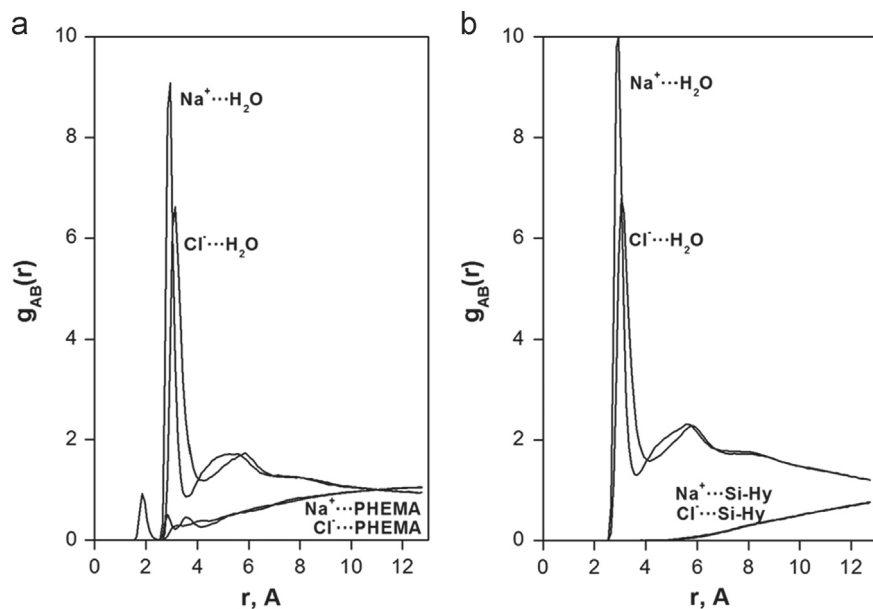

Fig. 4. Plots of pair correlation function between Na^+ and Cl^- ions and water molecules (black lines) and polymer molecules (red lines) in the pHEMA (a) and Si-Hy (b).

Fig. 5. Appearance of bulk material (gray), and open spaces (white) in the molecular structure of simulated pHEMA-based material at 10 wt% water content (up-left) and 37 wt% water content (up-right) and Si-Hy material (bottom-left) and (bottom-right) for the same water content, respectively. Diffusing molecules are also visible as O_2 in red, Cl^- in purple and Na^+ in green, while H_2O molecules were deleted for a better observation of the hydrophilic cavities.

Fig. 6. Plots of diffusion coefficient of oxygen for simulations in (a) pHEMA and (b) Si-Hy contact lens polymers of different water contents (10 and 40 wt%) as a function of Molecular Dynamics time.

resistance than the hydrophilic phase due to the small amount of water in its pores being considered that the free volume of those pores will enlarge as the water uptake in the hydrophilic phase increases and the whole polymer swells. Percolation then occurs when the enlarged hydrophilic pores form an interconnected network thus facilitating gas transport. In comparison with Si Hy, the diffusion of oxygen for Hy materials is carried out homogeneously through of the hydrophilic phase, and its increases with the water content.

3.3. MDS and experimental results of O_2 permeability

It is well known that oxygen permeability through Si Hy is higher than Hy [15,50,52]. However, the transport mechanism and how this is achieved are still a matter of debate within the scientific community. In this work we have addressed O_2 transport in polymeric materials used in CL production using MDS to obtain the diffusion of oxygen through different material configurations as presented in Table 2. The results of the simulations are compared with experimental results obtained following the procedure described in Section 2.1 and is shown in Table 1. The values of apparent permeability (P) and diffusion (D) coefficients experimentally obtained are given in five and seven columns of Table 1 as average (\pm SD) of five repeated measures. A close inspection of this table shows that our experimental values are closer to the coefficients reported by previous researchers [47–51]. As expected, materials containing siloxane moieties in their structure present oxygen permeability values 5–10 times higher than conventional hydrogel materials. As previously discussed by computing intermolecular pair correlations functions, MDS results agree with this observation showing that O_2 molecules diffuse mainly through the hydrophobic parts of the Si Hy materials while they are distributed in the hydrophilic parts of the Hy materials. Considering that the oxygen permeability of water is much lower than the oxygen permeability through the siloxane pores, it is

Table 3

Values of oxygen diffusion coefficient (D), solubility (S) and permeability (P) obtained from the simulations of conventional (pHEMA-based) hydrogels and Si-Hy materials at different equilibrium water contents (10–40 wt%).

Fig. 7. Oxygen diffusion coefficient in pHEMA-based (Δ) and Si-Hy (\circ) membranes as a function of the equilibrium water content of the polymer.

possible to explain the differences in experimental O_2 permeability between those two kinds of materials.

As expected the mean square displacement shows increasing values with time. For times large enough, the diffusive regime is reached and $\langle [R(t) - R(0)]^2 \rangle$ varies linearly with time, i.e. the slope of the $\log\langle [R(t) - R(0)]^2 \rangle$ vs. $\log(t)$ plot reaches unity and the diffusion coefficient may be obtained from Eq. (7). Values of the oxygen diffusion coefficient for simulations in Hy and Si Hy polymers of different water contents are displayed as a function of time in Fig. 6. All curves show a sharp decrease of the diffusion coefficient with increasing time and the value of this quantity remains nearly constant at both moderate and long times. The average values over the last 4 ns of D and its standard deviation obtained by simulations at temperatures of 37 °C (310 K) with different water content are collected in Table 3. It can be seen that the oxygen diffusion coefficient inside the hydrogels increases with increasing cell water contents.

However, a study of the variation of oxygen diffusion coefficient with water content of the lenses, such as is plotted in Fig. 7, shows a slope change at a water concentration of 25% in Si Hy L. This phenomenon is not observed in conventional pHEMA hydrogels and could be attributed to percolation phenomena. As we can see in Fig. 7, the amount of water content near to 30 wt% is expected to favour a completely segregation between hydrophilic and hydrophobic phases. In addition, as water concentrates in the

hydrophilic domain and pushes the volume of the polymer matrix to expand, free volume is created within the hydrophobic domain inducing the formation of pores with very low water content. The percolation of the hydrophobic phase enables the formation of a continuous pathway for the diffusion of oxygen. A close inspection of Fig. 7 shows great difference between the mechanisms of oxygen transport between Hy and Si Hy. It should be noted that the oxygen diffusion coefficient has a nonzero value when the water content is 0 wt% in Si Hy materials which is in agreement with previous determination of the oxygen transport through Si Hy materials in dry conditions [52].

The oxygen solubility was calculated with conformations obtained every 5 ps in MDS so that 100 conformations were selected using the modified particle insertion method. The insertion positions were 5×10^6 times randomly selected in simulation box and the solubility was calculated by Eqs. (8) and (9). Left part of Fig. 8 shows the solubility as a function of particles insertion number in the last conformation obtained by MDS for Hy and Si Hy matrices with 37 wt% of H₂O. Solubility values converged to a constant value after 3×10^6 particle insertions. Right part of Fig. 8 shows the solubility after the 5×10^6 insertions for all conformations obtained by MDS. High fluctuations of solubility values were observed in the first conformations possibly due to shorter time being insufficient to achieve stabilization in MDS, but eliminating the initial period leads to a stable value. The solubility was calculated as the average over the last 50 conformation obtained by MDS.

Table 3 shows the values obtained with our simulations for oxygen diffusion, solubility and permeability coefficients Hy and SiHy CL. A close inspection of Tables 1 and 3, shows a very good correlation between the values of oxygen diffusion obtained experimentally and MDS for lenses of similar water uptake.

Our experimental and MDS results are quite similar to those reported by other researchers [51]. In this sense, Chhabra et al. [51] have found experimentally that diffusion coefficients of oxygen in Polymacon (pHEMA) and Balafilcon A of are $6 \times 10^{-6} \text{ cm}^2/\text{s}$ and $15 \times 10^{-6} \text{ cm}^2/\text{s}$, respectively. Then, taking into account that the values of oxygen permeability for these lenses are respectively, around 8.4 and 99 Barrers, respectively, then the average values of apparent solubility of these materials must be $1.4 \times 10^{-5} \text{ cm}^3 (\text{O}_2)/\text{cm}^3$

cm^3 of polymer/mmHg and $6.6 \times 10^{-5} \text{ cm}^3 (\text{O}_2)/\text{cm}^3$ of polymer/mmHg, for pHEMA and Balafilcon A, respectively. The comparison between the solubility, diffusion and oxygen permeability coefficient obtained experimentally and MDS show good agreement either for Hy and Si Hy materials.

3.4. Transport of Cl⁻, Na⁺ ions and H₂O

The knowledge of transport of molecules absorbed in contact lenses as ionic molecules and water, provide a better understanding of whether a contact lens is physiologically compatible with the ocular surface. Though ionic diffusion in polymeric membranes is not a well understood phenomenon, this process presumably involves dissociation of the ions from the salt, subsequent transfer of the anion and cation to the aqueous medium, and finally, diffusion of the ions in the confined water within the polymer matrix. Therefore, ionic mobility will depend on water flux which is a critical parameter together with the water uptake by the lens. It is worth noting that both evaporation present during CL wear and electro osmotic drag processes have the potential to severely diminish the CL hydration, causing a significant increase of the ionic resistance. With this hypothesis, the diffusion coefficient of naked ions: Na⁺, Cl⁻ and H₂O absorbed were also evaluated by MDS.

In Fig. 9, we report the variation of the diffusion coefficient of H₂O and Na⁺ and Cl⁻ ions for pHEMA and Si Hy materials obtained from MDS. As can be seen in Fig. 9(a), the variation of the diffusion coefficient of water, Na⁺ and Cl⁻ increase with water content. However for Si Hy lenses, Fig. 9(b), the percolation phenomena occurs in all cases around 30 wt% water content, in which interconnected segregated phases co exist. On the other hand, the variation of the diffusion coefficient of Na⁺ and Cl⁻ is linked to water flow through the material. When the diffusion of water is high, the diffusion of ions will also be high and therefore, a better physiological behavior of the lens should be expected because ion diffusion has been shown to be critical for the metabolism of the cornea but also to warrant the movement of the lens on the eye avoiding adherence [48] and improve the comfort [53].

With the aim to compare the results obtained by simulation we also are determined experimentally the sodium permeability

Fig. 8. Plots of solubility as a function of particles insertion number in the last conformation obtained by MD simulations (left). solubility vs. molecular dynamics time(right), for pHEMA (a) and Si-Hy (b) systems.

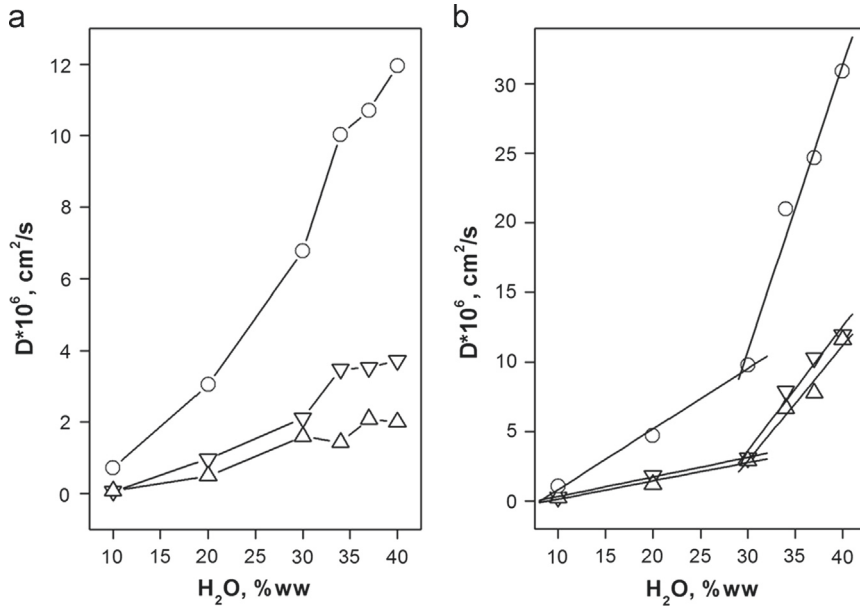

Fig. 9. Diffusion coefficients of H₂O (○), Cl⁻ (Δ) and Na⁺ (▽) in pHEMA-based (a) and Si-Hy (b) membranes as a function of the equilibrium water content of the polymer.

Fig. 10. Salt concentration in the receiving chamber as a function of time for Biofinity (●), PureVision (■), Acuvue2 (▲) and Proclear (●) lenses at 35 °C. In the permeation cell, donor volume and concentration is 16 mL and 0.1 M NaCl, respectively. The aperture communicating donor and receiving chambers is 8 mm of diameter, corresponding a sample area of 0.50 cm². In the inset we show the calibration curve correlating salt concentrations and conductivity has been measured and it is shown in the inset of Fig. 10 ($r^2=0.9997$). A value of 0.65 μ S corresponding to the background conductivity of our Milli Q water was subtracted from all the conductivity values obtained. The line represent adjust to experimental date (in all the cases the correlation coefficient is $r^2=0.9998$).

using the experimental procedure described in Section 2.2 [54]. The experimental values of permeability and diffusion coefficient of NaCl are obtained from Eqs. (5) and (6) following the experimental procedure described in Section 2.2. In Fig. 10 we plot the salt concentration of two conventional hydrogel and two Si Hy lenses (Proclear, Acuvue, PureVision[®] and Biofinity) in the receptor chamber as a function of time. Previously to the characterization of the salt transport across the samples, a calibration curve correlating salt concentrations and conductivity has been measured and it is shown in the inset of Fig. 10 ($r^2=0.9997$). A value of 0.65 μ S corresponding to the background conductivity of our Milli Q water was subtracted from all the conductivity values obtained.

In Table 4 we show the results of permeability and diffusion coefficient of the Na⁺ ions for all the lenses studied. From this values the salt partition coefficient, given by $k_m=P/D$, have also

Table 4

Values of apparent salt permeability (P), salt diffusion (D) and partition coefficient ($k_m=P/D$) for the hydrogel and Si-Hy lenses obtained following the technique described in Section 2.2. The errors of the apparent permeability and diffusion coefficients have been calculated from the parameters of the straight line that fits the experimental values taking into account that each measurement was repeated three times.

| Lens (commercial name) | $P (\times 10^7), \text{cm}^2/\text{s}$ | $D (\times 10^7), \text{cm}^2/\text{s}$ | k_m, au |
|-------------------------|---|---|------------------|
| Seequence | 18.4 ± 1.2 | 54 ± 11 | 0.34 ± 0.09 |
| Proclear | 32.8 ± 1.3 | 60 ± 12 | 0.55 ± 0.13 |
| Acuvue2 | 28.9 ± 1.2 | 55 ± 10 | 0.53 ± 0.12 |
| Newvues | 34.1 ± 1.3 | 58 ± 11 | 0.59 ± 0.13 |
| PureVision [®] | 6.7 ± 0.2 | 18 ± 3 | 0.37 ± 0.07 |
| Biofinity | 10.5 ± 0.3 | 14 ± 2 | 0.75 ± 0.13 |
| Acuvue Oasys | 0.97 ± 0.1 | 2.3 ± 0.8 | 0.42 ± 0.19 |
| Avaira | 6.0 ± 0.2 | 7.2 ± 1.5 | 0.83 ± 0.20 |

been also determined and their values are given in the fourth column of this table. A close inspection of Table 4 allows us to observe that the apparent Na⁺ permeability obtained for Si Hy lenses is about 3–4 times lower than that of Hy lenses, and the salt diffusion coefficient increases significantly with increasing water uptake. This should be expected considering that both D and k_m increase with increasing water uptake. For example for 36 wt% water content Si Hy material (lens PureVision), Na⁺ permeability, diffusion and salt partition coefficients are $6.7 \times 10^{-7} \text{cm}^2/\text{s}$, $1.8 \times 10^{-6} \text{cm}^2/\text{s}$ and 0.42, respectively. On the other hand, Hy materials (Seequence lens corresponding to Polymacon material) with 38.6 wt% water content show Na⁺ permeability, diffusion and salt partition coefficients of $18.4 \times 10^{-7} \text{cm}^2/\text{s}$, $5.4 \times 10^{-6} \text{cm}^2/\text{s}$ and 0.34, respectively. These results are in agreement with the results obtained by Cerretani et al. [55] where Si Hy materials have an apparent NaCl permeability lower than HEMA based materials, (see Fig. 1 in Reference [55]).

The values of water diffusion coefficient found in our work by MDS are higher in the case of Si Hy materials, four or five times compared to the experimental values, and lower for conventional hydrogels, such as we can see in Fig. 9, where the values of Na⁺ diffusion coefficient in Polymacon and Balafilcon A materials are included. A possible explanation for this is that the simulations never represent the actual system configuration, because the experimental

measurements are performed in aqueous medium where the boundary layer effect is often of great importance, however this effect is not considered in the configuration cell analyzed by the simulation process. Furthermore, simulations cannot mimic the entire composition of the lenses as this information is not completely known. Partition coefficient cannot be obtained by MDS, so it is not possible to compare them with the values experimentally obtained.

4. Conclusions

Oxygen transport in Hy and Si Hy was evaluated by MDS using a modified insertion particle method in two different kinds of materials: Hy and Si Hy. The structural difference between the two systems, make them ideal candidates to understand the different characteristics observed on the oxygen and ionic transport in CL. In Si Hy materials the aqueous and siloxane phases are separated suggesting a co continuous structure, and oxygen moves predominantly through the hydrophobic pores (siloxane domain).

The oxygen permeability in Si Hy materials used as CL is about one order of magnitude larger than that found for Hy materials. The value of the oxygen diffusion coefficient obtained by simulations is roughly similar to that experimentally found using potentiostatic techniques. The oxygen solubility coefficient is about six times higher for Si Hy materials compared to Hy. The coordination number between the fixed groups (SiO^-) and water in HEMA and the particles (O_2 , Cl^- and Na^+) is slightly larger than unity.

We observed a percolation phenomenon in the diffusion of oxygen, H_2O , Na^+ and Cl^- when the water content of the Si Hy lenses is about 30 wt%. This suggests that the compositions integrating Si Hy CL, increase both oxygen and water diffusion coefficients when the water content increases over 25–30 wt%.
